Description	Lithium-ion (Li-I) batteries store electricity through a reversible chemical reaction. The basic components are a container, electrodes, and an electrolyte. By loading the battery, the electricity is transformed into chemical energy, while during discharge, electrochemical reactions occur at the two electrodes generating a flow of electrons through an external circuit (DNV KEMA, 2013).										•

RL level 2020	TRL 9 Li-ion batteries are one of the most used technologies for electrochemical electricity storage (IRENA, 2015). While at large-scale, as of 2014, Li-ion batteries are still considered to be at the demonstration stage of technological development (JRC ETRI, 2014). However, the recent rapid development of Li-ion storage technology (including in both the telecommunications and automotive industry), leads to the expectation that Li-ion batteries for large-scale electricity storage will achieve a high TRL level by 2020.

	The potential for all battery types is high as there are no significant space or resource constraints, instead the demand for storage and costs are usually determining factors when it comes to potential installed capacity. As of 2015, Li-ion batteries have 0.2% of the utility-scale electricity storage market share, which is dominated by pumped hydro at 99% market share (IRENA, 2015). The market share is not included in the data set because it covers all utility-scale storage applications (both temporal and power applications) and the market share of Li-ion batteries for temporal storage is not yet clear.
